Notebook: Races vs Tournament

Last updated: 03 July, 2017

Abstract

This document contains data analysis for the paper "Races or Tournaments?".

1 Descriptive statistics

Create list of covariates to be used in regression model.

```
dat <- within(races, {</pre>
   year <- as.numeric(format(member_date, "%Y"))</pre>
   hours <- week1 + week2 + week3 + week4
    rating <- mm_rating
   maxrating <- mm_rating_max</pre>
   minrating <- mm_rating_min</pre>
    submissions <- mm_events
    avecodesub <- ave_nsub_past</pre>
    registrations <- mm_reg
    # svydate <- as.numeric(format(as.Date(startdate),'%d')) - 1</pre>
   lpaid <- log(paid)</pre>
    male <- gender == "Male"</pre>
    grad <- educ == "Doctorate/PhD" | educ == "Postgraduate/Master of arts"</pre>
    below30 <- age == "<20 years old" | age == "20-25 years old" |
        age == "26-30 years"
})
covars <- with(dat, data.frame(year, rating, volatility, maxrating,</pre>
    minrating, registrations, submissions, avecodesub, lpaid,
    nwins, ntop5, ntop10, risk, hours, male, regdate, timezone,
    grad, below30))
## Error in data.frame(year, rating, volatility, maxrating, minrating, registrations, : object 'regdate
Check covariates are balanced across treatment groups.
# FUNC to compute descriptive statistics
descriptives <- function(dat, treat = races$treatment) {</pre>
    balance.test <- function(x) {
       1 <- split(x, treat)</pre>
        kruskal.test(1)$p.val
    mu <- sapply(dat, mean, na.rm = TRUE)</pre>
    q50 <- sapply(dat, median, na.rm = TRUE)
    lo <- sapply(dat, min, na.rm = TRUE)</pre>
    hi <- sapply(dat, max, na.rm = TRUE)
    std <- sapply(dat, sd, na.rm = TRUE)</pre>
    pval <- sapply(dat, balance.test)</pre>
    n <- sapply(dat, function(x) sum(!is.na(x)))</pre>
    tab <- cbind(mu, q50, std, lo, hi, n, pval)
    colnames(tab) <- c("Mean", "Median", "St.Dev.", "Min", "Max",</pre>
        "Obs.", "P-value")
    return(tab)
tab <- descriptives(covars)</pre>
## Error in lapply(X = X, FUN = FUN, ...): object 'covars' not found
xtab <- xtable(tab)</pre>
## Error in xtable(tab): object 'tab' not found
digits(xtab) \leftarrow c(1, 1, rep(0, ncol(tab) - 2), 3)
## Error in ncol(tab): object 'tab' not found
```

Skill rating distribution

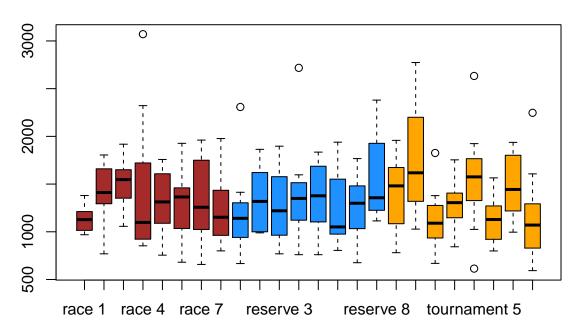

Figure 1: Skill rating distribution

```
align(xtab) <- c("@{{}1", rep("r", ncol(tab)))

## Error in ncol(tab): object 'tab' not found

caption(xtab) <- "Descriptive statistics"

## Error in caption(xtab) <- "Descriptive statistics": object 'xtab' not found

label(xtab) <- "summary"

## Error in label(xtab) <- "summary": object 'xtab' not found

render.xtable(xtab)

## Error in render.xtable(xtab): object 'xtab' not found

Show skill rating distribution is the same across treatments

colors <- c("brown", "dodgerblue", "orange")

boxplot(mm_rating ~ paste(treatment, room), data = races, col = rep(colors, each = 8))

title("Skill rating distribution")</pre>
```

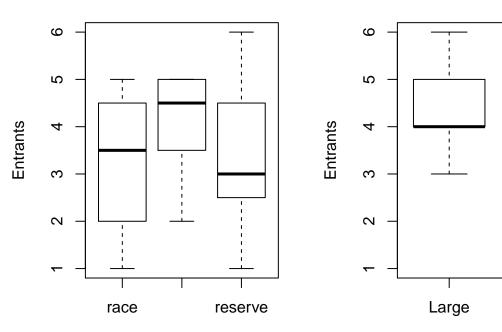

2 Entry

We examine differences in the count of room entrants between different competition styles and large and small room sizes.

Competition

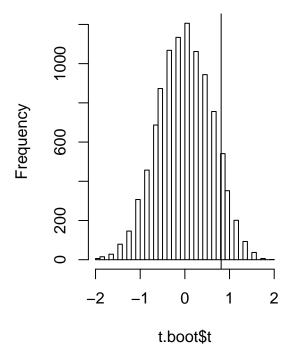

Room size

Small

```
diff(tapply(d$submit[i], d$treatment == "tournament", mean))
t.boot <- boot(counts, mean.diff, R = 9999, sim = "permutation")
hist(t.boot$t, breaks = "Scott")
abline(v = t.boot$t0)
mean(t.boot$t0 < t.boot$t)</pre>
## [1] 0.0690069
mean(t.boot$t0 <= t.boot$t)</pre>
## [1] 0.1231123
# Bootstrap Wilcox works better ...
# **********************************
# Test differences between small and large rooms
wilcox.test(submit ~ room_size, data = counts, exact = FALSE,
   correct = FALSE)
##
##
    Wilcoxon rank sum test
##
## data: submit by room_size
## W = 114, p-value = 0.01302
\#\# alternative hypothesis: true location shift is not equal to 0
```

Histogram of t.boot\$t

3 Individual propensity to submit

We then turn to the individual propensity to submit.

- We strongly reject differences in the propensity to submit between large and small rooms
- We do not have enough data for differences between competition styles

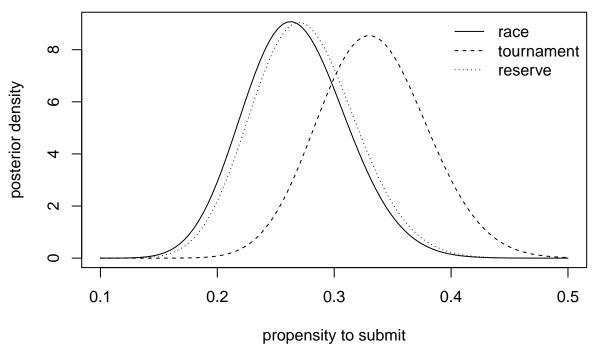

```
tab.size <- with(races, table(submit, room_size))</pre>
fisher.test(tab.size)
##
   Fisher's Exact Test for Count Data
##
##
## data: tab.size
## p-value = 1
## alternative hypothesis: true odds ratio is not equal to 1
## 95 percent confidence interval:
## 0.5689643 1.6912635
## sample estimates:
## odds ratio
## 0.9846648
# Test differences in individual propensity to submit ==>
# Largely not significant!!!
# Competition styles ==> no overall significance
tab <- with(races, table(submit, treatment))</pre>
fisher.test(tab)
##
##
   Fisher's Exact Test for Count Data
##
## data: tab
## p-value = 0.5255
## alternative hypothesis: two.sided
# Competition styles with target one-sided p-value is small
# but not significant
tab <- with(races, table(submit, treatment == "tournament"))</pre>
fisher.test(tab, alternative = "greater")
##
    Fisher's Exact Test for Count Data
##
##
## data: tab
## p-value = 0.1558
## alternative hypothesis: true odds ratio is greater than 1
## 95 percent confidence interval:
## 0.8435475
                      Inf
## sample estimates:
## odds ratio
     1.355339
```

One idea is to use Bayesian analysis. If we assume uniform priors, we can easily compute the posteriors in each treatment. Not sure what we can do with this result.

```
# Bayesian analysis Compute posteriors Beta(1 + success, 1 +
# n - success)
plot.posterior <- function(x, ...) {
    tab <- with(races, table(submit, treatment))
    param <- data.frame(tab + 1)
    index <- param$treatment == x
    shape <- param[index, ]
    curve(dbeta(x, shape$Freq[2], shape$Freq[1]), ...)
}

# PLOTs
plot.posterior("race", from = 0.1, to = 0.5, xlab = "propensity to submit",
    ylab = "posterior density")
plot.posterior("tournament", add = TRUE, lty = 2)
plot.posterior("reserve", add = TRUE, lty = 3)
title("theta | y \sim Beta(y + alpha, n-y + beta)")
legend("topright", legend = levels(races$treatment), lty = 1:3,
    bty = "n")</pre>
```

theta | y \sim Beta(y + alpha, n-y + beta)

Our model indicates a latent variable y^* appraoch.

- We first look at logistic regression for entry
- Then we look at regression for the scores
- Finally, we use a Tobit-type of approach to back up the primitives of our model

3.1 Binary regression model for entry

For each individual we observe a variable Z_i , an indicator for the "competition style" of the room person i was assigned to; a binary outcome variable Y_i , equal to 1 if person i made a valid code submission during the

competition [non example and with score greater than zero], and 0 otherwise; and a vector of covariates X_i , these include measures of individual ability, such as the skill rating, platform experience, time availability during the competition, and risk aversion.

Since the outcome variable was a binary indicator, we estimate the logistic regression model:

$$\Pr(Y_i = 1 \mid Z_i, X_i) = \text{logit}^{-1}(\beta_0 + \beta_1 Z_i + \sum \beta_k X_{i,k})$$

where $logit(\cdot)$ is the logistic distribution function. [Results are below]

```
# Create dataset for regression imputing missing values at
# random
dat.imp <- within(dat, {</pre>
   set.seed(25978)
   rating.100 <- rating/100
   hours.imp <- impute(hours, "random")</pre>
   risk.imp <- impute(risk, "random")</pre>
   grad.imp <- impute(grad, "random")</pre>
   male.imp <- impute(male, "random")</pre>
   below30.imp <- impute(below30, "random")</pre>
   timezone.imp <- impute(timezone, "random")</pre>
   expert <- cut(submissions, quantile(submissions[!is.na(rating)]),</pre>
       include = TRUE)
})
# First model has no covariates (i.e., $\gamma=0$)

##

Under the assumption of independence, the parameter β_1 is the average treatment effect of the competition style on participation. Correlation in decisions can be introduced with a quasi-binomial specification. The estimates have a structural interpretation. In terms of our contest theoretical model, due to the monotonicity of equilibrium, entry occurs only if the person i's ability is greater than a given threshold a_0 (the marginal type). This threshold is determined by the competition style among other things. Given in our experimental data one can assume that all else is equal except the competition style, this coefficient identifies the marginal type conditional on the competition style.

Here we try some more stuff ...

4 Timing of entry decision using panel data

Here we consider the panel of submissions. Next we look at the timing of submissions

```
data(scores)
# Create panel
create.panel <- function(z, id) {</pre>
   diffmin <- function(x) x - min(x)
   z$date <- z$timestamp \%>% as.Date \%>% as.numeric \%>% diffmin
   g <- expand.grid(date = seq(min(z$date), max(z$date)), coder_id = id,
      y = 0
   g2 <- rbind(g, z[, c("date", "coder_id", "y")])</pre>
   g2$date <- ifelse(g2$date < 3, 1, ifelse(g2$date < 5, 2,
      ifelse(g2$date < 7, 3, 4)))
   aggregate(y ~ date + coder_id, data = g2, FUN = sum)
scores.panel0 <- create.panel(scores, races$coder_id)</pre>
scores.panel <- merge(scores.panel0, races, by = "coder_id")</pre>
# Unconditional semi-parametric [Odds(first) = exp(alpha +
# beta * t )]
scores.panel$submit <- scores.panel$y > 0
clog <- clogit(submit ~ treatment + strata(date2), data = scores.panel)</pre>
## Error in strata(date2): object 'date2' not found
summary(clog)
## Error in summary(clog): object 'clog' not found

## Note:
```

We transform data in a panel with the date of the first submission. The probability of entry in a given date is modeled with a conditional logit. We find that the probability of entry in a given date decreases over time. (if it was at random 1/8 chances of having a submission in a given date). The estimated drop is about 13 percent from one date to the next (a reduction of above 100% from the first to the last date). Using interactions with treatment dummies, we find that the decrease in the probability of entry is negative in all treatments but it is about 25 percent in the race (with pvalue<0.05) it is only 8 (pval) and 6 (pval) percent for tournaments and reserve, respectively.

```

5 Analysis of scores

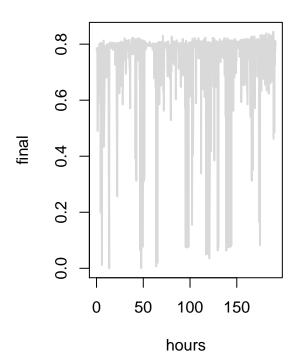

As a measure of the ability to make correct predictions of domain expert annotations we used the "F-score" defined as the harmonic mean of precision and recall: F = 2*(precision*recall)/(precision+recall)). This score was computed on 300 abstracts (100 of which were not disculssed to avoid overfitting) with about xxxx entities to correctly identify from a dictionary with xxxx labels.

```
baseline <- 0.792867
target <- 0.817866
winner <- 0.843962
```

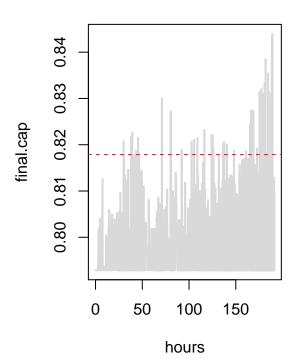

The baseline F-score achieved by NIH researchers was 0.792867. We set up a hard-to-reach F-score target for the race competition which was 0.817866 (about a 3 percent increase of the baseline). The winner achieved a score of 0.843962. This represents a 5.1095 percentage points increase compared to the baseline which can be regarded as a very remarkable improvement (more than 6 percent).

Figure below shows the provisional scores over the submission time. The left panel shows the raw scores that are very volitile because some preliminary submissions failed to compile or encountered other issues that either terminated the program resulting in a zero or lead to very low scores. This high volatility, however, does not reflect genuine variation in the quality of submissions. The right panel shows the scores capped from [below to reduce volatility due to experimentation with imperfect solutions].

##

- \bullet We observe $Y_1,...,Y_L$ participants for (l=1,...,L) rooms
- Each room has n_l registered competitors and room characteristics X_l (deadline, target, etc.).
- We assume that Y_l is distributed as a binomial variable with parameters n_l and $p(x_l, \theta)$ where $p(x, \theta)$ describes the probability for a competitor to participate in a room described by the vector x:

$$Y_l \sim \text{Binomial}(N_l, p(x_l, \theta)) \quad \text{for each } l = 1, ..., L.$$
 (1)

- In binomial linear models, the probability function $p(x, \theta)$ is related to a linear prediction through a one-to-one transformation called the link function (see XXXX). [Let see if our model is linear]
- Competitors have a latent ability variable a^* drawn from a common distribution $F_l(\cdot)$ (distributions may differ across rooms).
- At equilibrium, $Y_l = 1 \iff a^* \geq a_{0l}$ where a_{0l} is the marginal type for the room in room l.

• Zero profit condition is

$$R(a; F_l) = C(a, y_{0,l}, t_{0,l})$$

• Given $F_l(\cdot)$ the distribution of individual abilities in each room, the probability of entry is:

$$p(x_l, \theta) = 1 - F_l(a_{0l}) \tag{2}$$

The marginal type is determined by the zero profit condition:

$$R_l(m_l) = m_l^{\alpha} y_0^{\beta} t_0^{\gamma} \tag{3}$$

where the $R_l(m_l)$ is the expected revenue of the marginal type in a given room and it must be equal to the costs evaluated at the deadline t_0 and the target y_0 .

If we assume one single prize q = 1 (and we normalize the cost of meeting the deadline to one $t_0^{\gamma} = 1$) the zero profit condition becomes:

$$F_l(m_l)^{n_l-1} = m_l^{\alpha} y_0^{\beta} \tag{4}$$

By raising to the power $1/(n_l - 1)$ both sides of the equation, we obtain a structural relationship between the probability of entry (eq. XXX) and the marginal type, the number of registered competitors, and the cost function.

$$p(x_l, \theta) = 1 - \left[m_l^{\alpha} y_0^{\beta} \right]^{1/(n_l - 1)}$$
 with $\alpha \le -1, \beta \ge 1$.

As a result, one could use a "method of moments" to estimate the parameters $\theta = (\alpha, \beta, m_l)$ (y_0 and n_l are observed).

5.1 Estimation

First, we rewrite the probability $p(x,\theta)$ in the following way:

$$p(x_l, \theta) = 1 - \theta_1 x_l^{\theta_2}$$

where we denote the (observed) target by x_l and the vector of parameters by $\theta = (\theta_1, \theta_2)$ where $\theta_1 \equiv m_l^{\alpha/(n_l-1)}$ and $\theta_2 \equiv \beta/(n_l-1)$. Assume that $n_l = n$ for each l = 1, ..., L.

Let $Y_1, Y_2, ..., Y_L$ be the count of participants generated by our binomial-distribution model. The likelihood is:

$$\mathcal{L} = \prod_{l=1}^{L} \binom{n_l}{y_l} p(x_l, \theta)^{y_l} [1 - p(x_l, \theta)]^{n_l - y_l}$$

The log-likelihood is:

$$ll = \sum_{l=1}^{L} y_l \log(p(x_l, \theta)) + (n_l - y_l) \log(1 - p(x_l, \theta))$$

where we omit the binomial coefficient as it is a constant that does not affect estimation. Using our model into the above eqution:

$$ll = \sum_{l=1}^{L} y_l \log(1 - \theta_1 x_l^{\theta_2}) + (n - y_l) [\log(\theta_1) + \theta_2 \log(x_l)]$$

Let the summation be denoted by $\sum y_l = \bar{y}$. We can rewrite the ll expression:

$$ll = (Ln - \bar{y})\log(\theta_1) + \sum_{l=1}^{L} y_l \log(1 - \theta_1 x_l^{\theta_2}) + (n - y_l)\theta_2 \log(x_l)$$

First order conditions are:

$$\frac{\partial ll}{\partial \theta_1} = \frac{(Ln - \bar{y})}{\theta_1} - \sum_{l=1}^{L} y_l \frac{x_l^{\theta_2}}{1 - \theta_1 x_l^{\theta_2}} = 0$$

$$\frac{\partial ll}{\partial \theta_2} = \sum_{l=1}^{L} \left[-y_l \frac{x_l^{\theta_2} \theta_1 \log(x_l)}{1 - \theta_1 x_l^{\theta_2}} + (n - y_l) \log(x_l) \right] = 0.$$

Try with simulations

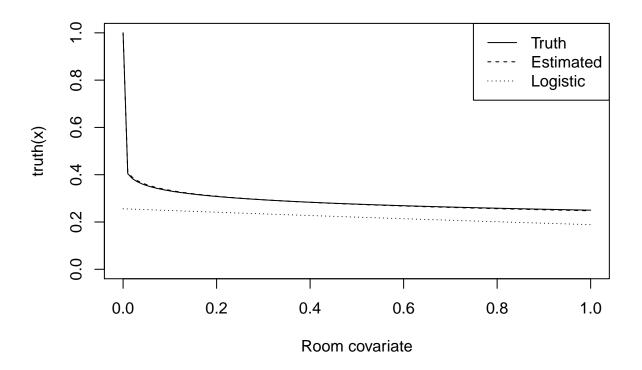

```
n <- 10
nsize <- 199
theta1 <- 0.75
theta2 <- 0.05
params <- c(theta1, theta2)
x <- runif(nsize)
p \leftarrow 1 - theta1 * x^theta2
# hist(prob, 100)
loglik <- function(theta, data) {</pre>
    theta1 <- theta[1]</pre>
    theta2 <- theta[2]</pre>
    x <- data$x
    y <- data$y
    n <- data$n
    p <- 1 - theta1 * x^theta2</pre>
    out <- dbinom(y, n, p, log = T)
    return(-sum(out))
# Simulate data
y <- rbinom(nsize, size = n, prob = p)
# Example: loglik(c(0.5, 0.9), data.frame(y, x, n))
# MLE estimation
dat <- data.frame(y, x, n)</pre>
theta.start <- runif(2)</pre>
mle.est <- optim(theta.start, loglik, data = dat)</pre>
thetahat <- mle.est$par
# Replications
out <- replicate(1000, {</pre>
    y <- rbinom(nsize, size = n, prob = p)
    dat <- data.frame(y, x, n)</pre>
    mle.est <- optim(theta.start, loglik, data = dat)$par</pre>
boxplot(t(out))
abline(h = params, col = 2)
```

```
truth <- function(x) 1 - params[1] * x^params[2]

# Now I can 'predictions' on what would happen with different
# 'x' distribution
prediction <- function(x) 1 - thetahat[1] * x^thetahat[2]

# Compare with logistic regression
N <- rep(n, nsize)
logistic <- glm(cbind(y, N) ~ x, family = binomial(logit))
prediction.logistic <- function(x) {
    yhat <- coef(logistic)[1] + coef(logistic)[2] * x
    exp(yhat)/(1 + exp(yhat))
}

# FIGURE
curve(truth, xlab = "Room covariate", ylim = c(0, 1))
curve(prediction, add = TRUE, lty = 2)
curve(prediction.logistic(x), add = TRUE, lty = 3)
legend("topright", c("Truth", "Estimated", "Logistic"), lty = 1:3)</pre>
```

6 Identification (old)

6.1 Example with the Uniform distribution

Imagine that the distribution F_{θ} is uniform on $(0, \theta)$ and the cost ability $c_a(x) = 1/x$. Then the zero profit condition (3) becomes

$$\left(\frac{m}{\theta}\right)^{n-1}m = \beta x_l \tag{5}$$

Solving for the marginal type gives:

$$m = \left(\beta x_l \theta^{n-1}\right)^{1/n} \tag{6}$$

So, the probability of participation (??) becomes

$$p(x_l, \theta) = 1 - F_{\theta}(m) \tag{7}$$

$$=1-\frac{\left(\beta x_l \theta^{n-1}\right)^{1/n}}{\theta}\tag{8}$$

$$=1-\left(\frac{\beta x_l}{\theta}\right)^{1/n}.\tag{9}$$

Because it is non-linear in its parameters, the model is not identifiable [need proof]. However, we can re-parametrize the model with $\beta/\theta \equiv \eta$ to make the parameter η identifiable.

6.2 Example with Beta distribution

In this example, we assume abilities are drawn from a lognormal distribution with parameters μ and σ .

6.3 Estimation

Our aim is to estimate the parameters θ and β and to evaluate whether costs are different between the three competition modes under study: race, tournament, tournament + requirement.

It is natural to estimate the parameters θ by maximum likelihood because the ability distribution (and therefore the distribution of the outcomes) is known. The estimation criterion used here is the maximization of the *deviance*.

The deviance is:

$$D(\theta) = -2\sum Y \log(\frac{Np(x,\theta)}{Y}) + (N-Y)\log(\frac{N-Np}{N-Y}). \tag{10}$$

Note that the deviance is a function of the likelihood (see xxx pg. xxx).

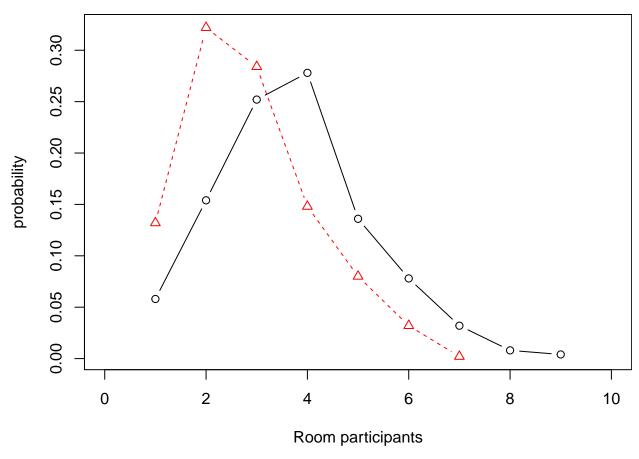

Figure 2: Simulated distribution of participants with uniform distribution. Parameters are $\eta = 0.1$ and n = 15. Data simulated 500 times. Dashed curve had higher costs $(x_l = 1.5)$ than the solid curve $(x_l = 0.5)$.

7 The model

We now generalize the contest game introduced by @moldovanu2001optimal to a situation where players simultaneously decide i) the quality and ii) how fast to produce a given output. Then we explore the problem of revenue maximization faced by a contest designer with preferences for both quality and time.

7.1 Basic setup

7.2 Equilibrium

In this section, we solve the model for the unique symmetric Bayesian Nash equilibrium of players.

7.2.1 Tournament

At equilibrium, players choose q_i and t_i by maximizing (??) given their beliefs about the equilibrium actions of the other players.

The key to characterization of the equilibrium is that $t_i = t_0$ is a (weakly) dominant strategy for each player. Indeed, any time strictly below the deadline does not affect the probability of winning but is costly in terms of effort, and any time strictly above the deadline gives a negative payoff.

Since players should avoid playing weakly dominated strategies, we have that $t_i = t_0$ for every i = 1, ..., n. Then it can be shown that, at equilibrium, the optimal quality is a one-to-one transformation of a player's ability according to some "bidding" function $b(\cdot)$. Hence, $Y_i = b(A_i)$. Since the distribution of A_i is known, one can use a change of variables formula to express the probability of winning in (??) in terms of the distribution F. Then, the first order condition of π with respect to quality gives the following differential equation in a_i (for every i = 1, ..., n):

$$\sum_{k=1}^{q} \hat{p}'_k(\phi(y_i) \mid \text{tournament}) \phi'(y_i) v_k = \beta y_i^{\beta-1} a^{\alpha} t^{\gamma}$$

with the boundary condition y(a) = 0.

At equilibrium we have $a = \phi(y)$. Thus, the differential equation is separable. After rearranging, we have:

$$\sum_{k=1}^{q} \phi(y_i)^{-\alpha} \hat{p}'_k(\phi(y_i) \mid \text{tournament}) \phi'(y_i) v_k = \beta y_i^{\beta-1} t^{\gamma}.$$

Integration of both sides with respect to ϕ gives:

$$\int_0^y \sum_{k=1}^q t^{-\gamma} v_k \phi(x)^{-\alpha} \hat{p}'_k(\phi(x) \mid \text{tournament}) \phi'(x) dx = \int_0^y \beta x^{\beta - 1} dx$$

Using the chain rule of derivatives

$$\int_a^b f(g(x))g'(x)dx = \int_{g(a)}^{g(b)} f(x)dx \qquad \text{(chain rule)}$$

the solution is

$$y(a_i) = \left[t_0^{-\gamma} \sum_{k=1}^q v_k \int x^{-\alpha} \hat{p}'_k(x) dx \right]^{1/\beta}$$
 (12)

An important property of (12) is that $y(a_i)$ has its lower bound in zero and its upper bound in

$$y(\bar{a}) = \left[t_0^{-\gamma} v_1 \left(\frac{\bar{a}^{-\alpha+1} - \underline{a}^{-\alpha+1}}{-\alpha+1} \right) \right]^{1/\beta}.$$

- Monotonicity of the equilibrium output quality implies that, for every i = 1, ..., n, the equilibrium expected payoff from the contest π_i^* depends on the rank of the player's ability relative to the others.
- Equilibrium payoffs do not depend on the elasticity β or γ , but only on α .
- When abilities are distributed over the unit interval, the equilibrium payoff for the highest ability player is $\pi(\bar{a}=1)=v_1(-\alpha)/(1-\alpha)$.

7.2.2 Equilibrium in a race

In a similar way, one can derive the equilibrium strategy in a race. Again the key observation is that any quality below the target gives a zero probability of winning and any quality above the target gives a constant probability of winning. Thus, player i's choice of quality is either zero (with $t_i = t_0$ by convention) or $y_i = y_0$. Then, the equilibrium xxx for player i is

$$t^*(a_i) = c_{\tau}^{-1} \left[c_{\tau}(t_0) + \frac{1}{c_y(y_0)} \left(\alpha \int_{a_i}^{\bar{a}} A'(z) dz + (1 - \alpha) \int_{a_i}^{\bar{a}} B'(z) dz \right) \right]$$
 (13)

where

$$A(x) = \frac{1}{c_a(x)} f_{(n-1:n-1)}(x)$$
(14)

and

$$B(x) = \frac{1}{c_n(x)} \left\{ \left[1 - F_{(n-1:n-1)}(x) \right] f_{(n-1:n-2)}(x) + f_{(n-1:n-1)}(x) F_{(n-1:n-2)}(x) \right\}. \tag{15}$$

An important property of XX is that $y^*(a_i)$ has its upper bound in XX and lower bound in XX. Again payoffs are xxxx. Hence, by setting to zero and solving for the ability, gives the marginal ability \underline{a} as

$$\underline{a} = h(n, V, F_A, C, d). \tag{16}$$

7.2.3 Tournament vs races

By comparing equilibrium xxx and xxx, we find that the race and the tournament do not (ex-post) dominate one another with respect to output quality. Whereas the race always dominates the tournament with respect to completion time. [This is only when the deadline is the same. Otherwise, there's always xxxx.] This result is stated below.

Proposition 1. There always exist an interval of abilities where the output quality is higher in the race than in the tournament. By contrast, every player takes less completion time in the race than in the tournament.

Proof. Marginal type has utility zero in a race but the same type has a strictly positive utility in the tournament. Since probability of winning is not different in the race or the tournament (the bid is a monotonic transformation of the individual ability or, in other words, rankings are virtually the same), expected payoffs in equilibrium differ only in the cost functions. Hence, to be an equilibrium, the player in the tournament should bid less than the player in the race to earn a strictly positive expected payoff. \Box

Let's make an example.

```
p <- plnorm # pdf individual abilities
r <- rlnorm # Simulate individual abilities
cy <- function(x) x^2 # Cost function performance
ct <- function(x) 2*exp(1-x) # Cost function timing</pre>
```

FIGURE 1. Equilibrium bids in a race and a tournament.

Implications. The above proposition applies only if the target is higher in a race than in a tournament. But what if the two competitions had the same target? In that case, tournaments and races have the same marginal type. Therefore, the performance of players in the tournament with reserve are always non-lower than those in the race. This does not imply that it is optimal to set the target. On the contrary, we will show that it is optimal to set an optimal target in a tournament that is below the optimal target in a race. Next section.

7.3 The contest designer's problem

Let us now focus on the contest designer's problem. Imagine the contest designer can choose the competition format to be either the race or the tournament. Imagine all other aspects of design are given. The prize structure α has been already chosen. There is a deadline t_0 , which is the same in both competition formats. [The quality requirement y_0^c in the tournament is smalle than that in the race $y_0^{\text{race}} > y_0^{\text{tournament}}$)] We will relax this assumption later to consider a more general setting where these variables are also part of the contest designer's problem.

The contest designer has an objective function that is increasing in the expected quality of the winning solution and decreasing in the corresponding time to completion. Here, to do not complicate exposition, we assume that the contest designer cares about the winning submission only: second placed efforts are not considered. [If the principal values the diversity of the solutions . . . but we assume it does not.]

XXX EQUATION XXXX

The optimal choice involves a comparison of the expected profits between the race and the tournament. Given xxxx, we can show that there will be a threshold on the cost of completion time $\hat{\tau}$ above which the race is a better choice than the tournament, and vice versa.

Proposition 2. There's a tau above which ...

Proof. In a tournament, the objective function is

$$R_{\text{tournament}} = \Pr(t_{(1:n)} \le t_0) \left\{ \int y^*(x \mid t_{(1:n)} \le t_0) dF_{n:n}(x) - \tau t_0 - 1 \right\}$$
$$= \int_{\hat{a}}^{\bar{a}} y^*(x) dF_{n:n}(x) - \tau t_0 - 1. \tag{17}$$

That is, the contest designer's objective function is the sum of the expected output quality for a given deadline, minus the cost τ of having the winner working on the task until completion (i.e., until the deadline), and the cost of the prize pool (recall the prize pool is normalized to one).

[Implicitly, you're assuming that the prize is always large enough to ensure positive effort.] [Second prize too is stochastic!!!!]

In a race, the objective function is

$$R_{\text{race}} = \Pr(a_{(N)} \ge \hat{a}) \left\{ y_0 - \alpha - \Pr(a_{(N-1)} \ge \hat{a})(1-\alpha) \right\} - \tau \int_{\hat{a}}^{\infty} t^*(x) dF_{N:N}(x)$$

$$= \left[1 - F_{N:N}(\hat{a}) \right] \left\{ y_0 - \alpha - \left[1 - F_{N-1:N}(\hat{a}) \right] (1-\alpha) \right\} - \tau \int_{\hat{a}}^{\infty} t^*(x) dF_{N:N}(x). \tag{18}$$

Note. $t^*(x) \le t_0$ for all x's. Thus, a lower bound for the above objective function can be computed:

$$R_{\text{race}} = [1 - F_{N:N}(\hat{a})] \{ y_0 - \alpha - [1 - F_{N-1:N}(\hat{a})](1 - \alpha) - \tau t_0 \}$$
(19)

An even simpler lower bound is rewriting the above expression as if $\alpha = 1$ (note if the real alpha was set 1 then also mtype would change and therefore setting alpha hits a lower bound only when mtype does xxxx when alpha is 1).

Note. $y^*(x)$ is lower than y_0 for all $a < \hat{a}$. Thus, a lower bound of the tournament's expression is

$$\overline{R_{\text{tournament}}} = [1 - F_{N:N}(\hat{a})]y_0 + \int_{\hat{a}}^{\infty} y^*(x)dF_{N:N}(x) - \tau t_0 - 1.$$
(20)

$$\frac{R_{\text{race}}}{R_{\text{tournament}}} \ge \overline{R_{\text{tournament}}}$$

$$[1 - F_{N:N}(\hat{a})](y_0 - 1 - \tau t_0) \ge [1 - F_{N:N}(\hat{a})]y_0 + \int_{\hat{a}}^{\infty} y^*(x)dF_{N:N}(x) - \tau t_0 - 1$$

$$-[1 - F_{N:N}(\hat{a})](\tau t_0 + 1) \ge \int_{\hat{a}}^{\infty} y^*(x)dF_{N:N}(x) - (\tau t_0 + 1)$$

$$F_{N:N}(\hat{a})(\tau t_0 + 1) \ge \int_{\hat{a}}^{\infty} y^*(x)dF_{N:N}(x)$$

$$\tau \ge \left[\frac{\int_{\hat{a}}^{\infty} y^*(x)dF_{N:N}(x)}{F_{N:N}(\hat{a})} - 1\right] \frac{1}{t_0}$$
(21)

End proof.

When the cost of time τ is sufficiently high, the race is preferred. Interestingly, the threshold is a function of the deadline to complete the job, as xxx. It also depends on the shape of xxxx.

7.3.1 Optimal minimum-entry

Now we turn to discuss the contest designer's choice of an optimal minimum requirement y_0 . So far, we have assumed that $y_0^{\text{race}} > y_0^{\text{tournament}}$. Now, we show that the assumption that xxxx is indeed an optimal choice of the contest designer. This is summarized in the next proposition.

Proposition 3. Suppose the contest designer can choose the target that max profits in both the race and the tournament. Then, the optimal y_0 in tournament is generally lower than that in a race.

To prove that it is indeed the case. We proceed in two steps. First, we assume that the contest designer does not care about minimizing the timing of the innovation by imposing $\tau = 0$. For simplicity, assume that $\alpha = 1$ (winner-takes-all). In a race, this means that the optimal target will be a value that makes equal the costs in terms of less participation versus the gains in terms of higher values of the winning solutions. Formally, the contest designer's problem in a race is

maximize
$$R^{\text{race}} = [1 - F_{N:N}(\hat{a})](y_0^{\text{race}} - 1).$$
 (22)

Note that \hat{a} depends on the target. This is clearly concave in y_0^{race} . Thus, the first order condition is also sufficient.

FOC
$$\Rightarrow -F'_{N:N}(\hat{a})\hat{a}'(y_0^{\text{race}} - 1) + [1 - F_{N:N}(\hat{a})] = 0.$$
 (23)

In a tournament, ...

maximize
$$R^{\text{race}} = \int_{\hat{a}}^{\infty} y^*(x, y_0) dF_{N:N}(x) - [1 - F_{N:N}(\hat{a})].$$
 (24)

Convexity is not sure. If not, then the optimal target is zero. Which is lower than the optimal target in a race.

Instead. If the objective function is (strictly) concave then there's an internal solution.

FOC
$$\Rightarrow \frac{d \int_{\hat{a}}^{\infty} y^{*}(x, y_{0}) dF_{N:N}(x))}{dy_{0}} + F'_{N:N}(\hat{a})\hat{a}' = 0$$

(by using Leibniz rule)
 $\Rightarrow -y^{*}(\hat{a}, y_{0})\hat{a}'F'_{N:N}(\hat{a}) + \int_{\hat{a}}^{\infty} \frac{\partial y^{*}(x, y_{0})}{\partial y_{0}} dF_{N:N}(x) - F'_{N:N}(\hat{a})\hat{a}' = 0$
 $\Rightarrow -y_{0}\hat{a}'F'_{N:N}(\hat{a}) + \int_{\hat{a}}^{\infty} \frac{\partial y^{*}(x, y_{0})}{\partial y_{0}} dF_{N:N}(x) - F'_{N:N}(\hat{a})\hat{a}' = 0.$ (25)

Using (23) with (25), the optimal target is the same in the race and the tournament only if

$$\int_{\hat{a}}^{\infty} \frac{\partial y^*(x, y_0)}{\partial y_0} dF_{N:N}(x) = [1 - F_{N:N}(\hat{a})].$$

$$\frac{\partial y^*(x, y_0)}{\partial y_0} = \frac{c'_y(y_0)}{c'_y(y^*(x, y_0))}.$$
(26)

Then.

- If $c_y(\cdot)$ is linear, we have that the ratio is one for all x.
- If $c_u(\cdot)$ is convex, then we have that it is less than one. If
- If $c_y(\cdot)$ is concave, then we have that it is higher than one.

As a result, if linear or convex the first order condition is lower than that in the race. Since the obj. function is concave (second order is decreasing), the target should be lower in a tournament than in a race to satisfy the first order condition. (a lower target increases the focs.). Conjecture. If $\tau > 0$, the y_0 in the race is higher.

7.4 Structural econometric model

Readings:

- The winner's curse, reserve prices, and endogenous entry: Empirical insights from eBay auctions
- Entry and competition effects in first-price auctions: theory and evidence from procurement auctions
- Auctions with entry

General two-step strategy:

- First step. Identify the marginal type from the data and the distribution of types.
- Second step. Using the estimated distribution of types.

Basic idea. Equilibrium condition gives:

$$y_i^* = y^*(a_i; F_{\mathcal{A}}). \tag{27}$$

with $y^*(\cdot)$ being an invertible function with ϕ denoting the inverse.

Hence the distribution of bids is

$$F_Y(y) = \Pr(y_i^* \le y) = \Pr(y^*(a_i) \le y) = \Pr(a_i \le \phi(y)) = F_{\mathcal{A}}(\phi(y)). \tag{28}$$

10.1 Theory

In the standard tobit model [@amemiya1985advanced], we have:

$$y_i = \begin{cases} y_l & \text{if } y_i^* < y_l \\ y_i^* & \text{if } y_i^* \ge y_l \end{cases}$$

Where $y^* = x\beta + \epsilon$, assuming disturbance $\epsilon \sim N(0, \sigma^2)$

Let denote the standard normal distribution by $\Phi(\cdot)$ and the density function by $\phi(\cdot)$. The likelihood is:

$$\mathcal{L} = \prod_{i}^{n} \left(\sigma^{-1} \phi \left(\frac{y_i - X_i \beta}{\sigma} \right) \right)^{I(y_i)} \left(1 - \Phi \left(\frac{X_i \beta - y_l}{\sigma} \right) \right)^{1 - I(y_i)}$$

where $I(\cdot)$ is an indicator function that is 1 when $y_i > y_l$ and 0 otherwise.

10.2 Application

```
require(AER)
# Example with left censoring
n <- 1000
yl <- 0.1
x1 \leftarrow runif(n)
x2 \leftarrow rchisq(n, 1)
betas <-c(0.25, -0.1)
simulate.tobit <- function(n, betas, yl, x1, x2) \{
   ystar <- rnorm(n, mean = cbind(x1, x2) %*% betas)</pre>
   y <- ifelse(ystar < yl, yl, ystar)
}
y \leftarrow simulate.tobit(n, betas, yl = 0.1, x1, x2)
summary(tobit(y ~ x1 + x2 - 1, left = y1))
